#### **Abstract**

In roadmap-based methods, such as the Probabilistic Roadmap Method (PRM) in deterministic environments or the Feedback-based Information RoadMap (FIRM) in partially observable probabilistic environments, a stabilizing controller is needed to guarantee node reachability in state or belief space. In belief space, it has been shown that the belief-node reachability can be achieved using stationary Linear Quadratic Gaussian (LQG) controllers, for linearly controllable systems. However, for nonholonomic systems such as unicycle model, belief reachability is a challenge. In this paper we construct a roadmap in information space, where the local planners in partially-observable space are constructed by utilizing a Kalman filter as an estimator along with a Dynamic Feedback Linearization-based (DFL-based) controller as the belief controller. As a consequence the task of belief stabilizing to the pre-defined nodes in the belief space is accomplished even for nonholonomic systems. Therefore, a query-independent roadmap is generated in belief space that preserves the "principle of optimality", required in dynamic programming solvers, while taking obstacles into account, this method serves as an offline POMDP solver for motion planning in belief space. Experimental results shows the efficiency of both individual local planners and the overall planner over information graph for a nonholonomic model.

#### I. Introduction

This work aims in providing a sampling-based feedback solution for the problem of nonholonomic motion planning in belief space, i.e., under motion and sensing unertainties.

Nonholonomic motion planning (NMP) deals with planning open-loop or feedback (closed-loop) plans for moving an object that is subject to nonholonomic constraints. Unicycle model is an important example of nonholonomic systems, which can model a large variety of systems ranging from differential drive and synchro drive single-body robots [1], to steerable needles in surgery [2]. One of the challenges in nonholonomic motion planning is stabilizing the system to a point. Thus, if we consider two basic motion tasks: point-to-point motion, which deals with driving a moving object from a given state/configuration to another given state/configuration, and trajectory following, that deals with following a trajectory in state/configuration space, then, in contrast to the holonomic case, the point-to-point motion in nonholonomic systems is a much more difficult task than trajectory tracking [3]. As mentioned, the main challenge is the state stabilization to the target node.

Motion planning under uncertainty (MPUU) is an instance of sequential decision making problem under uncertainty. Considering the uncertainty in object's motion and uncertainty in sensory readings, the state of system is not fully observable, and thus, is not available for decision making. In such a situation, a state estimation module can provide a probability distribution over the possible states of the system, and therefore decision making is performed in the space of these distributions, the so called information space (or belief space). Planning in the belief space in its most general form is formulated as a Partially Observable Markov Decision Process (POMDP) problem[4], [5]. However, only a very small class of POMDP problems can be solved exactly. In particular, planning, (i.e., solving POMDPs,) in continuous state, control, and observation spaces, where our problem resides, is a formidable challenge.

Sampling-based motion planning methods have shown great success in dealing with many motion planning problems in complex environments and are divided into two main classes: Roadmap-based (graph-based) methods such as the Probabilistic Roadmap Method (PRM) and its variants[6], [7] and tree-based methods such as methods in [8], [9]. In dealing with MPUU, roadmap-based methods have a desirable feature: since the solution of POMDP is a feedback over whole belief space, it does not depend on the initial belief and from any given belief it produces a best action. This property matches well with roadmap-based methods that are multi query so that a feedback can be defined on the graph, which produces the best action at each graph node. On the other hand, tree-based methods are usually query-dependent and rooted in the start point of the query.

Similar to motion planning in state space, in belief space motion planning, the basic motion tasks can be defined as: *point-to-point motion*, which deals with driving the belief of the moving object from a given belief to another given belief, and *trajectory following*, which deals with following a trajectory in belief space. Both these tasks are even more challenging in belief space than in state space. To construct a query-independent roadmap in belief space, point-to-point motion in belief space is required. A number of pioneering methods have been proposed in [10], [11], [12] for applying sampling-based ideas for motion planning in belief space. However, one challenge they all face is they do not support point-to-point motion functionality in belief space. Thus, they do not preserve the "optimal substructure property" [13] needed in the solving DP equation, or in Dijkstra's algorithm [14]. Therefore, the roadmap construction depends on the start point of the submitted query and hence a new roadmap has to be constructed for every query. Prentice *et al.*[10] and Huynh *et al.*[11] reuse a significant portion of the computation by using covariance factorization techniques to reduce the computation burden imposed by the query dependence.

In fully-observable environments, Generalized PRM [15] perform point-to-point motion under motion uncertainty. In partially observable environments, under motion and sensing uncertainty, the Feedback-based Information RoadMap (FIRM) [16], [17] utilizes feedback controllers for the purpose of belief stabilization, and hence embeds the point-to-point motion behaviour in belief space. As a consequence, the generated roadmap in belief space is query-independent and only needs to be constructed once. Also, the principle of optimality is preserved on FIRM, and the connection between its solution and the original POMDP can be established rigorously [16], [17]. It is also shown to be probabilistically complete [18]. FIRM is an abstract framework for planning in belief space, and a Linear Quadratic Gaussian-based (LQG-based) instantiation of FIRM is reported in [16], [17]. The main shortcoming of the LQG-based FIRM is that it only works for systems which are linearly controllable about a fixed node point. This condition excludes nonholonomic systems, which are not stabilizable to a fixed point under linear controllers.

The main contribution of this work is to present an instantiation of the abstract FIRM framework [16], [17] for nonholonomic systems using Dynamic Feedback Linearization-based (DFL-based) controllers. The DFL-based control of nonholonomic models is a well-established technique, but its usage in the belief space along with stationary Kalman filter to construct a Feedback Information RoadMap (FIRM) is both novel and powerful. This construct leads to a sampling-based feedback motion planner in belief space for nonholonomic systems, which shows very promising results in conducted experiments. It builds up on a PRM, where corresponding to each PRM node, we define a unique belief node and design a feedback controller with partial observations in such a way that the robot's belief is steered toward a pre-defined point in belief space independent of starting point. Using the KF as the estimator, and the DFL-based controller as the belief controller, we embed the point-to-point motion in belief space for nonholonomic systems. Thus, we can construct a roadmap in belief space independent of the

<sup>&</sup>lt;sup>1</sup>Principle of optimality represents the fact that the segments of optimal paths are in-themselves optimal. It is also called "optimal substructure property" [13]

query, which can be used efficiently for replanning purposes. Also, collision probabilities are seamlessly incorporated in the construction of planner.

### II. CONTROLLABILITY IN NONHOLONOMIC SYSTEMS

An implicit assumption in road-map based methods such as PRM is that on every edge there exists a controller to drive the robot from the start node of the edge to the end node of the edge or to an  $\epsilon$ -neighborhood of the end node, for some small  $\epsilon > 0$ . For a linearly controllable robot, a linear controller can locally track a PRM edge and drive the robot to its endpoint node. However, for a nonholonomic robot such as a unicycle, the linearized model at any point is not controllable, and hence, a linear controller cannot stabilize the robot to the PRM nodes. Consider the discrete unicycle model:

$$x_{k+1} = f(x_k, u_k, w_k) = \begin{pmatrix} \mathsf{x}_k + (V_k + n_v)\delta t \cos\theta_k \\ \mathsf{y}_k + (V_k + n_v)\delta t \sin\theta_k \\ \theta_k + (\omega_k + n_\omega)\delta t \end{pmatrix},\tag{1}$$

where  $x_k = (\mathsf{x}_k, \mathsf{y}_k, \theta_k)^T$  describes the robot state, in which  $(\mathsf{x}_k, \mathsf{y}_k)^T$  is the 2D position of the robot and  $\theta_k$  is the heading angle of the robot, at time step k. The vector  $u_k = (V_k, \omega_k)^T$  is the control vector consisting of linear velocity  $V_k$  and angular velocity  $\omega_k$ . The motion noise vector is denoted by  $w_k = (n_v, n_\omega)^T \sim \mathcal{N}(0, \mathbf{Q}_k)$ . Linearizing this system about the point (node)  $\mathbf{v} = (\mathsf{x}^p, \mathsf{y}^p, \theta^p)$ , one can conclude that the system is linearly controllable iff  $V^p > 0$ . Thus, in stabilizing the robot to a PRM node, where the nominal control is zero,  $u^p = (V^p, \omega^p)^T = (0, 0)^T$ , the system is not linearly controllable. Therefore, a linear controller cannot stabilize the unicycle to a PRM node. Moreover, based on the necessary condition in Brockett's paper [19], even a smooth time-invariant nonlinear control law cannot drive the unicycle to a PRM node, and the stabilizing controller has to be either discontinuous and/or time-varying.

On roadmaps in belief space, the situation is even more complicated, since the controller has to drive the robot to the  $\epsilon$ -neighborhood of a belief node in belief space. Again, if the linearized system is controllable, using a linear stochastic controller such as the stationary LQG controller, one can drive the robot belief to the belief node [16], [17]. However, if the linearized system about the desired point is not controllable, the belief stabilization, if possible, is much more difficult than state stabilization. Consider a unicycle robot, equipped with sensors measuring the range and bearings from a set of landmarks in the environment. Linearizing the motion and sensing models of this system for stabilization purposes, although we get a linearly observable system, but it is not a linearly controllable system. In this paper, we handle this situation by utilizing a DFL-based controller along with a Kalman filter to steer the system belief toward a pre-defined node in belief space.

#### III. MOTION PLANNING UNDER UNCERTAINTY

Partially Observable Markov Decision Processes (POMDPs) are the most general formulation for motion planning problem under motion and sensing uncertainties (In this paper, the environment map is assumed to be known). The solution of the POMDP problem is an optimal feedback (mapping)  $\pi$ , which maps the information (belief) space to the control space. Let us denote the state, control and observation at time step k by  $x_k$ ,  $u_k$ , and  $z_k$ , respectively, which belong to spaces  $\mathbb{X}$ ,  $\mathbb{U}$ , and  $\mathbb{Z}$ , respectively. The belief in stochastic setting is defined as the pdf the of the system state conditioned on the obtained information (measurements and controls) up to the k-th time step, i.e.,  $b_k = p(x_k|z_{0:k};u_{0:k-1})$  and  $\mathbb{B}$  denotes the belief space, containing all possible beliefs. It is well known that the POMDP problem can be posed as a belief MDP problem [20], [21], whose solution  $\pi$  is computed by solving the following Dynamic Programming (DP) equation:

$$J(b) = \min_{u} \{ c(b, u) + \int_{\mathbb{B}} p(b'|b, u) J(b') db' \},$$
 (2a)

$$\pi(b) = \arg\min_{u} \{ c(b, u) + \int_{\mathbb{B}} p(b'|b, u) J(b') db' \},$$
 (2b)

where  $J(\cdot): \mathbb{B} \to \mathbb{R}$  is the optimal cost-to-go function, p(b'|b,u) is the belief transition pdf under control u, and c(b,u) is the one-step cost of taking control u at belief b.

# A. FIRM: Feedback-based Information RoadMap

It is well known that the above DP equation is exceedingly difficult to solve since it is defined over an infinite-dimensional belief space. In this paper, we approach this problem through the FIRM framework [16], [17] and accordingly, transform the POMDP in (2) into a tractable MDP problem. In this section, we briefly present the abstract FIRM framework and in the next section we explain how we can make a concrete instantiation of this framework that works for nonholonomic systems. In FIRM, we aim to sample the belief space and compute the cost-to-go of the sampled beliefs instead of cost-to-go for all beliefs in the belief space. Then, we show that this sampling in belief space leads to an intractable belief SMDP problem, which can be arbitrarily well approximated by a tractable FIRM MDP on the FIRM nodes. The main tools in this transformation are the local feedback planners, which are designed to ensure that at decision making stages, we reach pre-defined FIRM nodes in belief space. It is worth noting that the power of the local feedback planners resides in the fact that each local planner

is a sequence of closed-loop policies (Macro-policies) that can steer the belief toward a predefined belief-node, as opposed to a macro-action[22], which is a sequence of actions, i.e., a sequence of open-loop policies, which are incapable of belief stabilization.

Underlying PRM: First a PRM is constructed in the state space, with nodes denoted by  $\mathcal{V} = \{\mathbf{v}^j\}_{j=1}^n$  and edges denoted by  $\mathcal{E} = \{\mathbf{e}_{ij}\}$ . Note that  $\mathcal{V}$  includes the goal node to whose vicinity we want to transfer the robot.

FIRM nodes: FIRM nodes are disjoint small sets in the belief space. Corresponding to each PRM node, we design a unique FIRM node. The FIRM node corresponding to  $\mathbf{v}^i$  is denoted by  $B^i \subset \mathbb{B}$ , whose actual construction depends on the choice of local controller and is discussed in Section IV. The set of all FIRM nodes is denoted by  $\mathbb{V} = \{B^i\}_{i=1}^n$ .

Local planners: We use the phrases "local planner" and "local controller" interchangeably in this manuscript. The local controller  $\mu(\cdot): \mathbb{B} \to \mathbb{U}$  is a feedback controller. The role of (i,j)-th local controller, denoted by  $\mu^{ij}$ , is to take a belief from the FIRM node  $B^i$  to the FIRM node  $B^j$ . We denote the set of local controllers by  $\mathbb{M} = \{\mu^{ij}\}$ . In other words,  $\mu^{ij}$  generates controls based on the belief at each stage, until the belief reaches the region  $B^j$ . Thus, the local controller  $\mu^{ij}$  has to be a proper policy with respect to the region  $B^j$  over initial region  $B^i$  as stated in the following property:

**Property 1.** (Reachability property of FIRM): For every PRM edge  $e_{ij}$ , there exists a controller  $\mu^{ij}$ , such that the pair  $(\mu^{ij}, B^j)$  is a proper pair over region  $B^i$ , i.e., for all  $b \in B^i$  we have  $\mathbb{P}(B^j|b, \mu^{ij}) = 1$ , in the absence of obstacles. In other words, in the obstacle-free environment, the feedback controller  $\mu^{ij}(\cdot)$  has to drive the belief state from  $B^i$  into a  $B^j$  in a finite time with probability one.

Satisfying reachability property of FIRM: In [16], [17] it is proved that using stationary LOG controllers as local planners for linearly controllable systems about a fixed point, Property 1 (reachability condition) is satisfied. However, As discussed in Section II, LQG controllers cannot satisfy Property 1 for nonholonomic systems. In Section IV we propose a way to construct the DFL-based local controllers and FIRM nodes such that under a mild assumption Property 1 is satisfied for nonholonomic models such as a unicycle. However, for the sake of completion of theoretical framework we can even make the method independent of any assumption: we set a deterministic maximum time  $T_{max}$ , such that if the reachability under the local controller is not achieved before  $T_{max}$ , we consider it as failure, i.e., the same as colliding with obstacles. However, in 100% of the conducted experimental runs, the DFL-based controller is successful in satisfying Property 1.

Roadmap of local controllers: Local planners are parametrized by underlying PRM edges. So, one can view the procedure as "sampling the local planners". Similar to roadmap-based methods in which the path is constructed by concatenating edges of the roadmap, in FIRM the policy is constructed by concatenating local feedback policies. At each FIRM node  $B^i$ , the set of local controllers that can be invoked is  $\mathbb{M}^i = \{\mu^{ij} \in \mathbb{M} | \exists \mathbf{e}_{ij} \in \mathcal{E} \}$ . However, it is worth noting that through this construction we still perform planning on continuous spaces, and do not discretize any of the state, control, or observation spaces.

Generalizing transition costs and probabilities: We generalize the concept of one-step cost  $c(b,u): \mathbb{B} \times \mathbb{U} \to \mathbb{R}$  to the concept of  $C(b,\mu): \mathbb{B} \times \mathbb{M} \to \mathbb{R}$ . The step cost  $C(b,\mu^{ij})$  represents the cost of invoking local controller  $\mu^{ij}(\cdot)$  at belief state b, i.e.,

$$C(b, \mu^{ij}) = \sum_{t=0}^{\mathcal{T}^{ij}} c(b_t, \mu^{ij}(b_t)|b_0 = b),$$

$$\mathcal{T}^{ij}(b) = \inf_{t} \{t|b_t \in B^j, b_0 = b\},$$
(3)

$$\mathcal{T}^{ij}(b) = \inf_{t} \{ t | b_t \in B^j, b_0 = b \}, \tag{4}$$

where  $\mathcal{T}^{ij}$  is a random stopping time denoting the time at which the belief state enters the region  $B^j$  under the controller  $\mu^{ij}$ . Similarly, we generalize the transition probabilities from  $p(b'|b,u): \mathbb{B}^2 \times \mathbb{U} \to \mathbb{R}_{\geq 0}$  to  $\mathbb{P}(\cdot|b,\mu): \mathbb{V} \times \mathbb{B} \times \mathbb{M} \to [0,1]$ , where  $\mathbb{P}(B^j|b,\mu^{ij})$  is the transition probability from b to  $B^j$  under the local planner  $\mu^{ij}$ .

Roadmap level transitions: Now, we transform the transition cost and probabilities to  $C^g: \mathbb{V} \times \mathbb{M} \to \mathbb{R}$  and  $\mathbb{P}^g: \{\mathbb{V}, F\} \times \mathbb{N}$  $\mathbb{V} \times \mathbb{M} \to [0,1]$  that are defined on the FIRM graph, i.e., over the finite space  $\{\mathbb{V},F\}$ . In other words,  $\mathbb{P}^g(B^j|B^i,\mu^{ij})$ and  $\mathbb{P}^g(F|B^i,\mu^{ij})$  are the transition probability from  $B^i$  to  $B^j$  and F, respectively, under the local planner  $\mu^{ij}$ . Similarly,  $C^g(B^i,\mu^{ij})$  denotes the cost of invoking local planner  $\mu^{ij}$  at FIRM node  $B^i$ . Accordingly,  $J^g: \{V,F\} \to \mathbb{R}$  is the cost-to-go function over the FIRM nodes, where  $J^g(F)$  is a user-defined suitably high cost for hitting obstacles. These roadmap level quantities are defined using the following "piecewise constant approximation", which is an arbitrarily good approximation for smooth transition probability and cost functions, and sufficiently small  $B^i$ 's:

$$\forall b \in B^{i}, \forall i, j \begin{cases} J^{g}(B^{i}) \coloneqq J(b_{c}^{i}) \approx J(b), \\ C^{g}(B^{i}, \mu^{ij}) \coloneqq C(b_{c}^{i}, \mu^{ij}) \approx C(b, \mu^{ij}), \\ \mathbb{P}^{g}(\cdot | B^{i}, \mu^{ij}) \coloneqq \mathbb{P}(\cdot | b_{c}^{i}, \mu^{ij}) \approx \mathbb{P}(\cdot | b, \mu^{ij}), \end{cases}$$

$$(5)$$

where  $b_c^i$  is a point in  $B^i$ , for example, its center, if  $B^i$  is a ball. The approximation essentially states that any belief in the region  $B^i$  is represented by  $b_c^i$  for the purpose of decision making.

*FIRM MDP*: By this construction of local planners and FIRM nodes, the original POMDP in (2) is reduced (for details see [17]) to the following finite-state MDP, called the FIRM MDP:

$$J^{g}(B^{i}) = \min_{\mu^{ij} \in \mathbb{M}^{i}} \{ C^{g}(B^{i}, \mu^{ij}) + J^{g}(F) \mathbb{P}^{g}(F|B^{i}, \mu^{ij}) + J^{g}(B^{j}) \mathbb{P}^{g}(B^{j}|B^{i}, \mu^{ij}) \},$$

$$\pi^{g}(B^{i}) = \arg \min_{\mu^{ij} \in \mathbb{M}^{i}} \{ C^{g}(B^{i}, \mu^{ij}) + J^{g}(F) \mathbb{P}^{g}(F|B^{i}, \mu^{ij}) + J^{g}(B^{j}) \mathbb{P}^{g}(B^{j}|B^{i}, \mu^{ij}) \},$$

$$(6a)$$

$$+ J^{g}(B^{j}) \mathbb{P}^{g}(B^{j}|B^{i}, \mu^{ij}) \},$$

$$(6b)$$

where, the solution of FIRM MDP  $\pi^g: \mathbb{V} \to \mathbb{M}$  is a feedback that returns the optimal local planner (as opposed to optimal action) for each FIRM node. It is worth noting that the approximation  $\pi^g(B^i) := \pi(b^i_c) \approx \pi(b)$  for all  $b \in B^i$ , results from the approximations in (5).

### B. Overall policy $\pi$

The overall feedback  $\pi$  is generated by combining the policy  $\pi^g$  on the graph and the local controllers  $\mu^{ij}$ s. Suppose at the k-th time step the active local controller and its corresponding stopping region are given by  $\mu_*^k \in \mathbb{M}$  and  $B_*^k \in \mathbb{V}$ . They remain the same, i.e.,  $\mu_*^{k+1} = \mu_*^k$ , and  $\mu_*^k$  keeps generating control signals based on the belief at each time step, until the belief reaches the corresponding stopping region,  $B_*^k$ , where the higher level decision making is performed over the graph by  $\pi^g$  that chooses the next local controller. For example if the controller  $\mu_*^k = \mu^{ij}$  is chosen, the stopping region is  $B_*^k = B^j$ . Once the state enters the stopping region  $B^j$ , the higher level decision making is performed over graph by  $\pi^g$  that chooses the next local controller, i.e.,  $\mu_*^{k+1} = \pi^g(B^j)$ . Thus, this hybrid policy is stated as follows:

$$\pi: \mathbb{B} \to \mathbb{U},$$

$$u_k = \pi(b_k) = \begin{cases} \mu_*^k(b_k), & \mu_*^k = \pi^g(B_*^{k-1}), \text{ if } b_k \in B_*^{k-1} \\ \mu_*^k(b_k), & \mu_*^k = \mu_*^{k-1}, & \text{if } b_k \notin B_*^{k-1} \end{cases}$$

$$(7)$$

Initial controller: Given the initial state is  $b_0$ , if  $b_0$  is in one of the FIRM nodes, then we just choose the best local controller using  $\pi^g$ . However, if  $b_0$  does not belong to any of the FIRM nodes, we first compute the mean state  $\mathbb{E}[x_0]$  based on  $b_0$  and then connect the  $\mathbb{E}[x_0]$  to the PRM nodes using a set of edges denoted by  $\mathcal{E}(0)$ . Afterwards, for every  $e_{ij} \in \mathcal{E}(0)$ , we design a local controller  $\mu^{ij}$ , and denote the set of newly added local controllers by  $\mathbb{M}(0)$ . Computing the transition cost  $C(b_0, \mu^{ij})$ , and probabilities  $\mathbb{P}(B^j|b_0, \mu^{ij})$ , and  $\mathbb{P}(F|b_0, \mu^{ij})$ , for invoking local controllers  $\mu^{ij} \in \mathbb{M}(0)$  at  $b_0$ , we choose the best initial controller  $\mu^0$  as:

$$\mu_*^0(\cdot) = \begin{cases} \arg\min_{\mu^{ij} \in \mathbb{M}(0)} \{C(b_0, \mu^{ij}) + \mathbb{P}(B^j | b_0, \mu^{ij}) J^g(B^j) + \\ \mathbb{P}(F | b_0, \mu^{ij}) J^g(F) \}, & \text{if } \nexists l, b_0 \in B^l \\ \pi^g(B^l), & \text{if } \exists l, b_0 \in B^l \end{cases}$$
(8)

# C. Summary

In summary, FIRM reduces the original POMDP into a tractable MDP on a finite subset of its nodes, which can be solved offline. Thus, performing online phase of planning (or replanning) is computationally feasible. It is also shown that this construct is probabilistic complete [18]. To exploit the generic FIRM framework, one has to find a proper  $(B, \mu)$  pairs as the FIRM nodes and local controllers. Also, there has to be a way of computing transition costs and probabilities. In the next section, we propose one such approach for nonholonomic systems, in which to design the local controllers  $\mu^{ij}$  and FIRM nodes  $B^i$ , we resort to a combination of a Kalman filter and a DFL-based controller, that can handle the nonholonomic systems in belief space. Moreover, we discuss how the transition costs  $C^g(B^i, \mu^{ij})$ , and the transition probabilities  $\mathbb{P}^g(\cdot|B^i, \mu^{ij})$ , can be evaluated in DFL-based FIRM. Finally, we solve the corresponding FIRM MDP and provide the algorithms for offline construction of DFL-based FIRM and online planning with it.

#### IV. DFL-BASED FIRM CONSTRUCTION

In this section, we construct a FIRM, in which local controllers are composed of Kalman Filter as the estimator, and Dynamic Feedback Linearization-based (DFL-based) controllers as the belief controller. Accordingly, we design reachable FIRM nodes  $B^j$ , and local planners  $\mu^{ij}$ , required in (6). Then we discuss how the transition probabilities  $\mathbb{P}^g(\cdot|B^i,\mu^{ij})$ , and costs  $C^g(B^i,\mu^{ij})$  in (6) are computed. We start by defining notation needed for dealing with Gaussian beliefs.

Gaussian belief space: Let us denote the estimation vector by  $x^+$ , whose distribution is  $b_k = p(x_k^+) = p(x_k|z_{0:k})$ . Denote the mean and covariance of  $x^+$  by  $\widehat{x}^+ = \mathbb{E}[x^+]$  and  $P = \mathbb{E}[(x^+ - \widehat{x}^+)(x^+ - \widehat{x}^+)^T]$ , respectively. Denoting the Gaussian belief space by  $\mathbb{GB}$ , every function  $b(\cdot) \in \mathbb{GB}$ , can be characterized by a mean-covariance pair, i.e.,  $b \equiv (\widehat{x}^+, P)$ . Abusing notation, we also show this using "equality relation", i.e.,  $b = (\widehat{x}^+, P)$ .

Information history: As discussed in partially-observable environments, the decision making at k-th time step is made based on the observation history  $z_{0:k}$  up to time step k and the control history  $u_{0:k-1}$  up to time step k-1. Thus, in partially observable environment, a controller is a mapping from information history to the control space  $\mu_k: \mathbb{Z}^{k+1} \times \mathbb{U}^k \to \mathbb{U}$ , i.e.,  $u_k = \mu_k(z_{0:k}, u_{0:k-1})$ . However, usually the design of the controller in partially-observable environments is decomposed into two tasks: i) designing an estimator that generates belief based on information history  $b_k = \overline{\tau}(z_{0:k}, u_{0:k-1})$  (or recursively  $b_k = \tau(b_{k-1}, z_k, u_{k-1})$ ) and ii) designing a belief controller that generates control signal based on the available belief, which here by abusing notation it is also shown by  $\mu$ , i.e.,  $u_k = \mu(b_k)$ . In designing LQG controller, this decomposition leads to designing a Kalman filter as the estimator and an LQR as the controller, whose combination preserves the optimality of the overall local controller. However, in many cases this decomposition may lead to a suboptimal solution, which is inevitable since the designing an optimal controller in partially-observable environments is a challenging task.

Unicycle control with partial information: In [16], [17] the optimal LQG controller is utilized for the construction of local controllers in FIRM. However, it is only limited to the models which are linearly stabilizable to a point in state space, which excludes the class of nonholonomic systems such as unicycle model. Here, we combine the Kalman filter and a DFL-based controller to construct a controller for the unicycle mode with partial information. This construct is a suboptimal design for the controller in partially-observable environment. However, it is very efficient in practice, and shows a promising solution for constructing a Feedback-based Information RoadMap (FIRM) for nonholonomic systems such as the unicycle model.

#### A. Estimator Design

We adopt the Kalman Filter (KF) as the state estimator, which is vastly utilized for localizing unicycle robot [21]. Thus, the belief dynamics  $b_{k+1} = \tau(b_k, u_k, z_{k+1})$  comes from the Kalman filtering equations. In Appendix A, we review the Kalman Filtering and its stationary behaviours in detail. Here, we only discuss the limiting belief behaviour under the stationary KF (SKF).

State Space Model: Consider a PRM node v. Let us denote the linear (linearized) system about the node v by the tuple  $\Upsilon = (\mathbf{A}, \mathbf{B}, \mathbf{G}, \mathbf{Q}, \mathbf{H}, \mathbf{M}, \mathbf{R})$  that represents the following state space model:

$$x_{k+1} = \mathbf{A}x_k + \mathbf{B}u_k + \mathbf{G}w_k, \quad w_k \sim \mathcal{N}(\mathbf{0}, \mathbf{Q})$$
 (9a)

$$z_k = \mathbf{H}x_k + \mathbf{M}v_k, \qquad v_k \sim \mathcal{N}(\mathbf{0}, \mathbf{R}).$$
 (9b)

Consider a stationary KF (SKF), which is designed to estimate the state of the system in (9). Let us also define the matrix  $\check{\mathbf{Q}}$  such that  $\mathbf{G}\mathbf{Q}\mathbf{G}^T = \check{\mathbf{Q}}\check{\mathbf{Q}}^T$ . Now, consider the class of systems, that satisfy the following property:

**Property 2.** The pair  $(A, \check{Q})$  is a controllable pair [20], and the pair (A, H) is an observable pair [20].

**Lemma 1.** Given Property 2, the estimation covariance under the SKF, designed for the system in (9), converges to the matrix  $P_s$ , independent of its initial covariance:

$$P_{s} = P_{s}^{-} - P_{s}^{-} \mathbf{H}^{T} (\mathbf{H} P_{s}^{-} \mathbf{H}^{T} + \mathbf{M} \mathbf{R} \mathbf{M}^{T})^{-1} \mathbf{H} P_{s}^{-},$$
(10)

where,  $P_s^-$  is the unique symmetric positive semidefinite solution of the following Discrete Algebraic Riccati Equation (DARE):

$$P_{k+1}^{-} = \mathbf{A}(P_k^{-} - P_k^{-} \mathbf{H}^T (\mathbf{H} P_k^{-} \mathbf{H}^T + \mathbf{M} \mathbf{R} \mathbf{M}^T)^{-1} \mathbf{H} P_k^{-}) \mathbf{A}^T + \mathbf{G} \mathbf{Q} \mathbf{G}^T.$$

$$(11)$$

Proof: See [20].

The estimation mean, however, evolves randomly, as it is a function of obtained observations. In SKF, the evolution of estimation mean is as follows:

$$\widehat{x}_{k+1}^{+} = (I - \mathbf{K}\mathbf{H})\mathbf{A}\widehat{x}_{k}^{+} + (I - \mathbf{K}\mathbf{H})\mathbf{B}u_{k} + \mathbf{K}z_{k+1} + (I - \mathbf{K}\mathbf{H})(I - \mathbf{A})\mathbf{v},$$
(12)

where,  $\mathbf{K} = P_s^- \mathbf{H}^T (\mathbf{H} P_s^- \mathbf{H}^T + \mathbf{M} \mathbf{R} \mathbf{M}^T)^{-1}$ .

#### B. Belief controller design

The belief system is an underactuated system, i.e., the dimension of control space is less than the dimension of belief space. However, we can have full control of the estimation mean, while based on Lemma 1 the estimation covariance under the SKF, tends to  $P_s$ . As a result, if we design a feedback controller to control the estimation mean towards node  $\mathbf{v}$  in state space, and assuming the system remains in the valid linearization region of the SKF (which is a reasonable assumption), then the whole belief will approach toward  $b_c = (\mathbf{v}, P_s)$  in the belief space. Considering a stopping region in belief space, whose interior contains  $b_c$ , the belief process under the feedback control will hit the stopping region in a finite time.

For a nonholonomic system such as the unicycle model, the system is not linearly controllable. Thus, we resort to the original nonlinear model, and utilize a Dynamic Feedback Linearization-based (DFL-based) controller to control the estimation mean for the nonholonomic unicycle model. The nonlinear form of (12) is:

$$\widehat{x}_{k+1}^{+} = f(\widehat{x}_{k}^{+}, u_{k}, 0) + \mathbf{K}\widetilde{z}_{k+1}, \tag{13}$$

where,  $\tilde{z}_{k+1}$  is the observation error, defined as

$$\widetilde{z}_{k+1} = h(f(x_k, u_k, w_k), v_{k+1}) - h(f(\widehat{x}_k^+, u_k, 0), 0)$$

$$\approx \mathbf{H} \mathbf{A} \widehat{e}_k^+ + \mathbf{H} \mathbf{G} w_k + \mathbf{M} v_{k+1}, \tag{14}$$

in which, the function h is the observation model that maps the states to observations, i.e.,  $z_k = h(x_k, v_k)$ , where  $v_k$  models the zero-mean Gaussian sensing noise. Random variable  $\widehat{e}_k^+$  is the estimation error defined by  $\widehat{e}_k^+ = x_k - \widehat{x}_k^+$ . Note that  $\widehat{e}_k^+$  is not measurable and thus acts like a noise in equations. The approximation in (14) results from linearizing functions h and f. The important point is that the equation in the right hand side of (14) does not depend on  $u_k$ . Thus, the term  $\mathbf{K}\widetilde{z}_{k+1}$  in (13) acts like a control-independent perturbation affecting the system. Therefore, we adopt a controller to control the unicycle model, which is effectively robust to the noise injected by  $\mathbf{K}\widetilde{z}_{k+1}$ . Obviously, the implicit assumption is that motion and sensing uncertainties are not so large to take the system out of the valid linearization region, which is a reasonable practical assumption. The controller of choice is a DFL-based controller proposed in [3], as it offers a robust behaviour with respect to disturbances. Moreover, it provides an exponentially fast stabilization procedure, and has a natural, and smooth, transient performance. Experimental results verifies the robustness of this controller to the above-mentioned disturbance  $\mathbf{K}\widetilde{z}_{k+1}$ .

To construct the DFL-based controller for unicycle model, first we transform the system state such that the target node coincides with the origin, i.e., if we denote  $\mathbf{v} = (\mathbf{v}_{\mathbf{x}}, \mathbf{v}_{\mathbf{y}}, \mathbf{v}_{\theta})$  and  $\widehat{x}_k^+ = (\widehat{\mathbf{x}}_k^+, \widehat{\mathbf{y}}_k^+, \widehat{\theta}_k^+)$ , we can transfer the system state as:

$$\begin{pmatrix} \breve{\mathbf{x}}_{k}^{+} \\ \breve{\mathbf{y}}_{k}^{+} \end{pmatrix} = \begin{pmatrix} \cos \mathbf{v}_{\theta} & -\sin \mathbf{v}_{\theta} \\ \sin \mathbf{v}_{\theta} & \cos \mathbf{v}_{\theta} \end{pmatrix}^{-1} \begin{pmatrix} \widehat{\mathbf{x}}_{k}^{+} - \mathbf{v}_{x} \\ \widehat{\mathbf{y}}_{k}^{+} - \mathbf{v}_{y} \end{pmatrix}$$
(15a)

$$\check{\theta}_k^+ = \widehat{\theta}_k^+ - \mathbf{v}_\theta \tag{15b}$$

Now the controller has to drive the  $\breve{x}_k^+ = (\breve{\mathbf{x}}_k^+, \breve{\mathbf{y}}_k^+, \breve{\boldsymbol{\theta}}_k^+)$  to the origin.

Ignoring the disturbance term in estimation mean dynamics, and assuming  $\widehat{x}_{k+1}^+ = f(\widehat{x}_k^+, u_k, 0)$ , we compute the estimation mean derivative in the last time step, based on the previous control signal  $u_{k-1} = (V_{k-1}, \omega_{k-1})$ :

$$\begin{pmatrix} \dot{\mathbf{x}}_{k-1}^+ \\ \dot{\mathbf{y}}_{k-1}^+ \\ \dot{\boldsymbol{\theta}}_{k-1}^+ \end{pmatrix} = \begin{pmatrix} V_{k-1}\cos\check{\boldsymbol{\theta}}_{k-1}^+ \\ V_{k-1}\sin\check{\boldsymbol{\theta}}_{k-1}^+ \\ \omega_{k-1} \end{pmatrix}$$
(16)

Accordingly, we compute the intermediate controls:

$$u_1' = -k_{p1} \ddot{\mathbf{x}}_{k-1}^+ - k_{d1} \dot{\ddot{\mathbf{x}}}_{k-1}^+ \tag{17}$$

$$u_2' = -k_{p2}\ddot{\mathbf{y}}_{k-1}^+ - k_{d2}\dot{\ddot{\mathbf{y}}}_{k-1}^+ \tag{18}$$

where, as described in [3], the condition on the gains are  $k_{pi}$ ,  $k_{di} > 0$  for i = 1, 2 and also  $k_{d1}^2 - 4k_{p1} = k_{d2}^2 - 4k_{p2} > 0$  and  $k_{d2} - k_{d1} > 2(k_{d2}^2 - 4k_{p2})^{-5}$ .

Finally, we compute the control signal at time step k:

$$V_k = V_{k-1} + (u_1' \cos \check{\theta}_{k-1}^+ + u_2' \sin \check{\theta}_{k-1}^+) \delta t \tag{19}$$

$$\omega_k = (u_2' \cos \check{\theta}_{k-1}^+ - u_1' \sin \check{\theta}_{k-1}^+) V_{k-1}^{-1}$$
(20)

Therefore, the controller, parametrized by the target point  $\mathbf{v}$ , receives current estimation mean  $\widehat{x}_k^+$  and the previous control  $u_k$  to generate the next control  $u_{k+1}$ . We show this mapping by  $u_{k+1} = \mu(\widehat{x}_k^+, u_k)$ .

### C. Designing FIRM Nodes $\{B^j\}$

FIRM Nodes: As mentioned, to construct a FIRM, we first construct its underlying PRM, characterized by its nodes and edges  $\{\{\mathbf{v}^j\}, \{\mathbf{e}^{ij}\}\}$ . Linearizing the system about the PRM node  $\mathbf{v}^j$  results in a linear system  $\Upsilon^j = (\mathbf{A}^j, \mathbf{B}^j, \mathbf{G}^j, \mathbf{Q}^j, \mathbf{H}^j, \mathbf{M}^j, \mathbf{R}^j)$ :

$$x_{k+1} = \mathbf{A}^j x_k + \mathbf{B}^j u_k + \mathbf{G}^j w_k, \quad w_k \sim \mathcal{N}(\mathbf{0}, \mathbf{Q}^j)$$
(21a)

$$z_k = \mathbf{H}^j x_k + \mathbf{M}^j v_k, \qquad v_k \sim \mathcal{N}(\mathbf{0}, \mathbf{R}^j)$$
 (21b)

where  $w_k$  and  $v_k$  are motion and measurement noises, respectively, drawn from zero-mean Gaussian distributions with covariances  $\mathbf{Q}^j$  and  $\mathbf{R}^j$ . Then, we design a stationary Kalman filter  $\tau^j$  and a DFL-based belief controller  $\mu^j$  corresponding

to the system  $\Upsilon^j$ . The controller  $\mu^j$  is called the *j*-th *node-controller*. Accordingly, we choose the belief nodes  $B^j$  such that  $B^j$  is an  $\epsilon$ -ball in belief space, centered at  $b_c^j \equiv (\mathbf{v}^j, P_s^j)$ , where  $P_s^j$  is the stationary covariance of the SKF designed for the system  $\Upsilon^j$ , computed using (10):

$$B^{j} = \{b \equiv (x, P) : \|x - \mathbf{v}^{j}\| < \delta_{1}, \|P - P_{s}^{j}\|_{m} < \delta_{2}\},$$
(22)

where  $\|\cdot\|$  and  $\|\cdot\|_m$  denote suitable vector and matrix norms, respectively. The size of FIRM nodes are determined by  $\delta_1$  and  $\delta_2$ , which are sufficiently small to satisfy the approximation in (5). Based on Lemma 1, the condition  $\|P_k - P_s^j\|_m < \delta_2$  is satisfied in after a deterministic finite time k > N and based on the adopted DFL design, which has a global attractive behaviour in the state space the condition  $\|x - \mathbf{v}^j\| < \delta_1$  is satisfied in some finite random time. In experiments, it is shown that this time is short and the controller can take the estimation mean to its target region considerably fast.

# D. PLQG-based Local Controllers $\mu^{ij}$

The role of the local controller  $\mu^{ij}$  is to drive the belief from the node  $B^i$  to node  $B^j$ . To construct the local controller  $\mu^{ij}$ , we precede the node-controller  $\mu^j$ , with a so called edge-controller  $\overline{\mu}_k^{ij}$ .

Edge-controller: The main role of the edge-controller  $\overline{\mu}_k^{ij}$  is that it takes the belief at node  $B_i$  and drives it to the vicinity of the node  $B^j$ , where it hands over the system to the node-controller  $\mu^j$ , which in turn takes the system into a FIRM node  $B_i$ . As opposed to the point-stabilization procedure, if we linearize the unicycle model along the PRM edge  $e^{ij}$ , where the nominal linear velocity is greater than zero, the unicycle is linearly controllable. As a result, we use a time-varying LQG controller to track the edge  $e^{ij}$ .

Local controllers: Thus, overall, the local controller  $\mu^{ij}$  is the concatenation of the edge-controller  $\overline{\mu}_k^{ij}$  and the node-controller  $\mu^j$ . By this construct, the expected stopping time of the node-controller decreases as the initial belief of the node-controller is closer to the target node  $B^j$ , due to the usage of the edge-controllers.

#### E. Transition probabilities and costs

In general, it can be a computationally expensive task to compute the transition probabilities  $\mathbb{P}(\cdot|B^i,\mu^{ij})$  and costs  $C(B^i,\mu^{ij})$  associated with invoking local controller  $\mu^{ij}$  at node  $B^i$ . However, owing to the offline construction of FIRM, it is not an issue in FIRM. We utilize sequential Monte-carlo methods [23] to compute the collision and absorption probabilities. For the transition cost, we first consider estimation accuracy to find the paths, on which the estimator, and consequently, the controller can perform better. A measure of estimation error is the trace of estimation covariance. Thus, we use  $\Phi^{ij} = \mathbb{E}[\sum_{k=1}^{\mathcal{T}} \operatorname{tr}(P_k^{ij})]$ , where  $P_k^{ij}$  is the estimation covariance at the k-th time step of the execution of local controller  $\mu^{ij}$ . The outer expectation operator is useful in dealing with the Extended Kalman Filter (EKF), whose covariance is stochastic[24], [25]. Moreover, since we are also interested in faster paths, we take into account the corresponding mean stopping time, i.e.,  $\widehat{\mathcal{T}}^{ij} = \mathbb{E}[\mathcal{T}^{ij}]$ , and the total cost of invoking  $\mu^{ij}$  at  $B^i$  is considered as a linear combination of estimation accuracy and expected stopping time, with suitable coefficients  $\xi_1$  and  $\xi_2$ .

$$C(B^i, \mu^{ij}) = \xi_1 \Phi^{ij} + \xi_2 \widehat{\mathcal{T}}^{ij}. \tag{23}$$

# F. Construction of PLQG-based FIRM and Planning With it

The crucial feature of FIRM is that it can be constructed offline and stored, independent of future queries. Moreover, owing to the reduction from the original POMDP to an n-state MDP on belief nodes, the FIRM MDP can be solved using standard DP techniques such as value/policy iteration to yield the optimal policy  $\pi^g$  that picks the optimal local planner  $\mu^* = \pi^g(B^i)$  at each FIRM node  $B^i$  among all controller  $\mu \in \mathbb{M}(\alpha,i)$ . Algorithm 1 details the construction of FIRM. Given that the FIRM graph is computed offline, the online phase of planning (and replanning) on the roadmap becomes very efficient and thus, feasible in real time. If the given initial belief  $b_0$  does not belong to any  $B_i$ , we create a singleton set  $B_0 = b_0$ . To connect the  $B_0$  to FIRM, we first, compute the expected value of the robot state, i.e.  $\mathbb{E}[x_0]$  using its distribution  $b_0$  and add the  $\mathbb{E}[x_0]$  to the PRM nodes, and connect it to the PRM graph. The set of newly added edges going from  $\mathbb{E}[x_0]$  to the nodes on PRM are called  $\mathcal{E}(0)$ . We design the local controllers associated with each edge in  $\mathcal{E}(0)$  and call the set of them as  $\mathbb{M}(0)$ . Then choosing a local controller in  $\mathbb{M}(0)$ , the belief enters one of FIRM nodes, if no collision occurs. Thus, given the current node, we use policy  $\pi^g$  defined in (6) over FIRM nodes to find  $\mu^*$ , and pick  $\mu^*$  to move the robot into  $B(\mu^*)$ . Algorithm 2 illustrates this procedure.

#### V. EXPERIMENTAL RESULTS

In this section, we illustrate the results of FIRM construction on a simple PRM. As a motion model, we consider the nonholonomic unicycle model whose kinematics is given in (1). As the observation model, in experiments, the robot is

# Algorithm 1: Offline Construction of DFL-based FIRM

```
1 input: Free space map, X_{free}
2 output : FIRM graph \mathcal{G}
3 Construct a PRM with nodes \mathcal{V} = \{\mathbf{v}^j\}, and edges \mathcal{E} = \{\mathbf{e}^{ij}\}, where i, j = 1, \dots, n;
4 forall the PRM nodes \mathbf{v}^j \in \mathcal{V} do
        Design the node-controller (DFL-based) \mu^j to stabilize the system to \mathbf{v}^j;
        Compute the FIRM node center b_c^j = (\mathbf{v}^j, P_s^j) using (10);
        Construct FIRM node B^j using (22) centered at b_c^j;
8 Collect all FIRM nodes \mathbb{V} = \{B^j\};
9 forall the (B^i, e^{ij}) pairs do
10
        Design the edge-controller \overline{\mu}_k^{ij}, as discussed in Section IV-D;
        Construct the local controller \mu_k^{ij} by concatenating edge-controller \overline{\mu}_k^{ij} and node-controller \mu_k^j;
11
        Set the initial belief b_0 equal to the center of B^i, based on the approximation in (5);
12
        Generate sample belief paths b_{0:\mathcal{T}} and state paths x_{0:\mathcal{T}} induced by controller \mu^{ij} invoked at B^i;
13
        Compute the transition probabilities \mathbb{P}^g(F|B^i,\mu^{ij}) and \mathbb{P}^g(B^j|B^i,\mu^{ij}) for all \gamma and transition cost C^g(B^i,\mu^{ij});
14
15 Collect all local controllers \mathbb{M} = \{\mu^{ij}\};
16 Compute cost-to-go J^g and feedback \pi^g over the FIRM by solving the DP in (6);
17 \mathcal{G} = (\mathbb{V}, \mathbb{M}, J^g, \pi^g);
18 return \mathcal{G};
```

# Algorithm 2: Online Phase Algorithm (Planning with DFL-based FIRM)

```
1 input: Initial belief b_0, FIRM graph \mathcal{G}, Underlying PRM graph
2 if \exists B^i \in \mathbb{V} such that b_0 \in B^i then
       Choose the next local controller \mu^{ij} = \pi^g(B^i);

11 while B^i \neq B_{aoal} do
        while (\nexists B^j, s.t., b_k \in B^j) and "no collision" do
12
            Apply the control u_k = \mu_k^{ij}(b_k) to the system;
13
            Get the measurement z_{k+1} from sensors;
14
            if Collision happens then return Collision;
15
            Update belief as b_{k+1} = \tau(b_k, \mu_k^{ij}(b_k), z_{k+1});
16
        Update the current FIRM node B^i = B^j;
17
        Choose the next local controller \mu^{ij} = \pi^g(B^i);
18
```

equipped with exteroceptive sensors that provide range and bearing measurements from existing radio beacons (landmarks) in the environment. The 2D location of the j-th landmark is denoted by  $L_j$ . Measuring  $L_j$  can be modeled as follows:

$$\begin{aligned}
 ^{j}z &= [\parallel^{j}\mathbf{d}\parallel, \operatorname{atan2}({}^{j}d_{2}, {}^{j}d_{1}) - \theta]^{T} + {}^{j}v, \quad {}^{j}v \sim \mathcal{N}(\mathbf{0}, {}^{j}\mathbf{R}), \\
 ^{j}\mathbf{R} &= \operatorname{diag}((\eta_{r}\parallel^{j}\mathbf{d}\parallel + \sigma_{b}^{r})^{2}, (\eta_{\theta}\parallel^{j}\mathbf{d}\parallel + \sigma_{b}^{\theta})^{2}), 
 \end{aligned} \tag{24}$$

where  ${}^{j}\mathbf{d} = [{}^{j}d_{1}, {}^{j}d_{2}]^{T} := [{}^{1}x, {}^{2}x]^{T} - L_{j}$ . The uncertainty (standard deviation) of sensor reading increases as the robot gets farther from the landmarks. The parameters  $\eta_{r} = \eta_{\theta} = 0.3$  determine this dependency, and  $\sigma_{b}^{r} = 0.01$  meter and  $\sigma_{b}^{\theta} = 0.5$  degrees are the bias standard deviations. A similar model for range sensing is used in [10]. The robot observes all  $N_{L}$  landmarks at all times and their observation noises are independent. Thus, the total measurement vector is denoted by  $z = [{}^{1}z^{T}, {}^{2}z^{T}, \cdots, {}^{N_{L}}z^{T}]^{T}$  and due to the independence of measurements of different landmarks, the observation model for all landmarks can be written as z = h(x) + v, where  $v \sim \mathcal{N}(\mathbf{0}, \mathbf{R})$  and  $\mathbf{R} = \text{diag}({}^{1}\mathbf{R}, \cdots, {}^{N_{L}}\mathbf{R})$ .

Figure 1(a) shows a simple environment with nine radio beacons, which are shown by the black stars. A PRM is constructed in the 3D space of  $(x, y, \theta)$  with 46 nodes and 102 edges. However, only the (x, y) portion of the all elements are shown in Fig.1(a). Each 2D node in 1(a) corresponds to several 3D nodes, only one of which is shown in Fig.1(a), with a blue triangle, whose number is written in red. To construct the FIRM nodes, we first solve the corresponding DARE's on each PRM node and design its corresponding DFL-based node-controller. Then, we pick the node centers  $b_c^j = (\mathbf{v}^j, P_s^j)$ , some of which are drawn in Fig.1(a). The covariance matrices  $P_s^j$  are shown by blue ellipses that represent their  $3\sigma$  bound. Finally, to handle the error scale difference in position and orientation variables, we construct the FIRM nodes based on the component-wise version of (22), as follows:

$$B^{j} = \{b = (x, P) | |x - \mathbf{v}^{j}| < \epsilon, |P - P_{s}^{j}| < \Delta\},$$

$$(25)$$

where  $|\cdot|$  and  $\dot{<}$  stand for the absolute value and component-wise comparison operators, respectively. We set  $\epsilon = [0.8, 0.8, 5^{\circ}]^T$  and  $\Delta = \epsilon \epsilon^T$  to quantify the  $B^j$ 's.

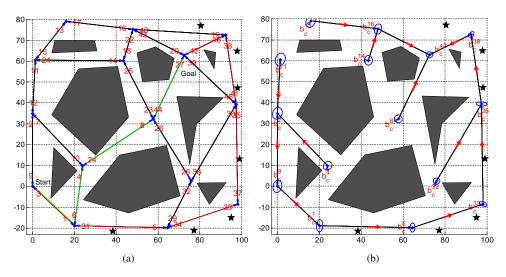

Fig. 1. A sample PRM, with numbered nodes. Seven landmarks are shown by black stars and obstacles are shown by gray polygons. (a) Node 9 is the start node and nodes 20, 27, 39, and 42 are goal nodes. Shortest path and the most-likely path under FIRM policy are shown in green and red, respectively. (b) The center of FIRM node, i.e.,  $b_c$  is drawn for a selected number of PRM nodes. The feedback  $\pi^g$  is visualized for those FIRM nodes by red arrows.

After designing FIRM nodes and local controllers, the transition costs and probabilities are computed in the offline construction phase. Here, we use sequential weighted Monte-carlo based algorithms [23] to compute these quantities. In other words, for every  $(B^i, \mu^{ij})$  pair, we perform M runs and accordingly approximate the transition probabilities  $\mathbb{P}^g(B^j|B^i, \mu^{ij})$ ,  $\mathbb{P}^g(F|B^i, \mu^{ij})$ , and costs  $C^g(B^i, \mu^{ij})$ . A similar approach is detailed in [17]. Table I shows these quantities along the resulting path under FIRM policy Fig.1(a), where M=101 and the coefficients in (23) are  $\xi_1=0.98$  and  $\xi_2=0.02$ . Along some edges, none of 101 particles have collided with obstacles and thus the collision probability is approximated by a value less than 1/101=0.0099. The expected value and standard deviation of the time it takes for the controller to drive the belief into the target node is also reported in table I, which reflects the efficiency of the DFL-based controller. Table II shows the same quantities for the edges along the shortest path. Comparing these two tables, it is obvious that the path returned by FIRM policy is safer, in the sense of collision probability, and most informative, in the sense of localization uncertainty, when compared to the shortest path.

TABLE I Computed costs for several pairs of node-and-controller using 101 particles along the path returned by  $\pi^g$ .

$(B_i,\mu^{ij})$ pair	$B_{9}, \mu^{9,1}$	$B_1,\mu^{1,5}$	$B_5, \mu^{5,33}$	$B_{33}, \mu^{33,35}$	$B_{35}, \mu^{35,38}$	$B_{38}, \mu^{38,42}$
$\mathbb{P}^{g}(F B_{i},\mu^{ij})$	15.3846%	7.6923%	< 0.99%	< 0.99%	< 0.99%	15.3846%
$\Phi^{ij}$	4.5967	1.9831	0.68936	1.6048	0.58705	0.53226
$\mathbb{E}[\mathcal{T}^{ij}]$	144.4545	217.3077	86.1538	161.2308	73	180.5455
$\sigma[\mathcal{T}^{ij}]$	66.7224	28.2396	9.109	5.7757	2.7433	40.6924

Plugging the computed transition costs and probabilities into (6), we can solve the DP problem and compute the policy  $\pi^g$  on the graph. This process is performed only once offline, independent of the starting point of the query. Fig. 1(b) shows the policy  $\pi^g$  on the constructed FIRM in this example. Indeed, at every FIRM node  $B^i$ , the policy  $\pi^g$  decides which local controller should be invoked, which in turn aims to take the robot belief to the next FIRM node.

TABLE II Computed costs for several pairs of node-and-controller using 101 particles along the shortest path.

$(B_i,\mu^{ij})$ pair	$B_9, \mu^{9,1}$	$B_1, \mu^{1,4}$	$B_4, \mu^{4,8}$	$B_8, \mu^{8,27}$
$\mathbb{P}^{g}(F B_i,\mu^{ij})$	15.3846%	38.4615%	46.1538%	38.4615%
$\Phi^{ij}$	4.5967	2.0181	2.8001	2.1664
$\mathbb{E}[\mathcal{T}^{ij}]$	144.4545	168.375	127.2857	111.25
$\sigma[\mathcal{T}^{ij}]$	66.7224	50.3841	12.9192	38.1042

Thus, the online part of planning is quite efficient, i.e., it only requires executing the controller and generating the control signal, which is an instantaneous computation. An important consequence of the feedback  $\pi^g$  is efficient replanning. In other words, since  $\pi^g$  is independent of query, if due to some unmodeled large disturbance, the robot's belief deviates significantly from the planned path, it suffices to bring the robot back to the closest FIRM node and from there  $\pi^g$  drives the robot to the goal region as shown in Fig. 1(b). We show the resulted path under policy  $\pi^g$ , in red in Fig. 1(a). The shortest path is also illustrated in Fig. 1(a) in green. It can be seen that the path returned by the best policy detours from the shortest path to a path along which the filtering uncertainty is smaller, and it is easier for the controller to avoid collisions.

#### VI. CONCLUSION

In this paper, we propose a sampling-based roadmap in belief space for nonholonomic motion planning. The crucial feature of the roadmap is that it preserves the "optimal substructure property," and establishes a rigorous connection with the original POMDP problem that models the problem of planning under uncertainty. The method lends itself to the FIRM framework. Exploiting the properties of Kalman filter and DFL-based controllers, the local planners in FIRM are designed such that the belief node reachability is achieved for systems with nonholonomic constraints. As a result, the roadmap provides a sampling-based feedback solution for nonholonomic systems in belief space.

# APPENDIX A STATIONARY KALMAN FILTERING

In this section, we first discuss the system linearization around the planned point, and then discuss the Stationary Kalman Filtering (SKF) procedure. Consider the nonlinear partially-observable state-space equations of the system as follows:

$$x_{k+1} = f(x_k, u_k, w_k), \quad w_k \sim \mathcal{N}(0, Q_k)$$
 (26a)

$$z_k = h(x_k, v_k), \quad v_k \sim \mathcal{N}(0, R_k) \tag{26b}$$

and consider a planned state point  $x^p$ , to whose vicinity the controller has to drive the system. If the system state reaches the  $x^p$ , it is assumed that the system remains there with zero control,  $u^p = 0$ , i.e.,

$$x^p = f(x^p, 0, 0) (27)$$

The role of a closed-loop stochastic controller, during the state regulation, is compensating robot deviations from the desired point due to the noise effects and driving the robot close to the desired point. When only some imperfect information of the state  $x_k$  is available, an estimator can make the estimate  $x_k^+$  of the state based on the available partial observations  $z_{0:k}$  up to the current time. Accordingly, a controller can generate the control signal based on the estimated value of the state, i.e. belief. Based on separation principle [20], in linear system with Gaussian noises, the above minimization in is equivalent to performing two separate minimizations that lead to the LQG controller. However, in nonlinear systems, this procedure leads to a suboptimal design.

In the following, we first discuss the linearization of a nonlinear model and then we discuss how the stationary Kalman filtering for this linearized system.

Model linearization: Given a desired point  $x^p$ , we linearize the dynamics and observation model in Eq. (26), as follows:

$$x_{k+1} = f(x^p, 0, 0) + A_s(x_k - x^p) + B_s(u_k - 0) + G_s w_k, \quad w_k \sim \mathcal{N}(0, Q_s)$$
 (28a)

$$z_k = h(x^p, 0) + H_s(x_k - x^p) + M_s v_k, \quad v_k \sim \mathcal{N}(0, R_s)$$
 (28b)

where

$$A_{k} = \frac{\partial f}{\partial x}(x^{p}, 0, 0), \quad B_{s} = \frac{\partial f}{\partial u}(x^{p}, 0, 0), \quad G_{s} = \frac{\partial f}{\partial w}(x^{p}, 0, 0),$$

$$H_{s} = \frac{\partial h}{\partial x}(x^{p}, 0), \quad M_{s} = \frac{\partial h}{\partial v}(x^{p}, 0)$$
(29)

Now, let us define the following errors:

• Main error:  $e_k = x_k - x^p$ .

- SKF error (estimation error):  $\widetilde{e}_k = x_k \widehat{x}_k^+$ , where  $\widehat{x}_k^+ = \mathbb{E}[x_k^+] = \mathbb{E}[x_k|z_{0:k}]$ .
   Belief controller error:  $\widehat{e}_k^+ = \widehat{x}_k^+ x^p$ .

Note that these errors are linearly dependent:  $e_k = \hat{e}_k^+ + \tilde{e}_k$ . Also, defining  $\delta u_k = u_k$  and  $\delta z_k = z_k - z^p := z_k - h(x^p, 0)$ , we can rewrite above linearized models as follows:

$$e_{k+1} = A_s e_k + B_s \delta u_k + G_s w_k \tag{30a}$$

$$\delta z_k = H_s e_k + M_s v_k \tag{30b}$$

Stationary Kalman Filter: In SKF, we aim to provide an estimate of the system's state based on the available partial information we have obtained until time k, i.e.,  $z_{0:k}$ . The state estimate is a random vector denoted by  $x_k^+$ , whose distribution is the conditional distribution of the state on the obtained observations so far, which is called belief and is denoted by  $b_k = p(x_k^+) = p(x_k|z_{0:k})$ . In the Gaussian case, the belief can only be characterized by its mean and covariance, i.e.,  $b_k \equiv (\hat{x}_k^+, P_k)$ . Thus, in the Gaussian case, we can write:

$$b_k = p(x_k^+) = p(x_k|z_{0:k}) = \mathcal{N}(\widehat{x}_k^+, P_k) \Leftrightarrow b_k \equiv (\widehat{x}_k^+, P_k)$$
(31)

$$\widehat{x}_{k}^{+} = \mathbb{E}[x_{k}|z_{0:k}], \quad P_{k} = \mathbb{C}[x_{k}|z_{0:k}]$$
(32)

where  $\mathbb{E}[\cdot|\cdot]$  and  $\mathbb{C}[\cdot|\cdot]$  are the conditional expectation and conditional covariance operators, respectively.

SKF consists of two steps at every time stage: prediction step and update step. In the prediction step, the mean and covariance of prior  $x_k^-$  is computed. For the system in Eq. (30) prediction step is:

$$\widehat{e}_{k+1} = A_s \widehat{e}_k^+ + B_s \delta u_k \tag{33}$$

$$P_{k+1}^{-} = A_s P_k^{+} A_s^{T} + G_s Q_s G_s^{T} (34)$$

In the update step, the mean and covariance of posterior  $x_k^+$  is computed. For the error system in Eq. (30), the update step is:

$$K_k = P_k^- H_s^T (H_s P_k^- H_s^T + M_s R_s M_s^T)^{-1}$$
(35)

$$\widehat{e}_{k+1}^{+} = \widehat{e}_{k+1}^{-} + K_{k+1} (\delta z_{k+1} - H_s \widehat{e}_{k+1}^{-})$$
(36)

$$P_{k+1}^{+} = (I - K_{k+1}H_s)P_{k+1}^{-}$$
(37)

Note that

$$\hat{x}_{k}^{+} = x^{p} + \hat{e}_{k}^{+}, \quad P_{k} = P_{k}^{+}$$
 (38)

In SKF, if  $(A_s, H_s)$  is an observable pair and  $(A_s, \check{Q}_s)$  is a controllable pair, where  $G_sQ_sG_s^T = \check{Q}_s\check{Q}_s^T$  then the prior and posterior covariances  $P_k^-$  and  $P_k$  and the filter gain  $K_k$ , all converge to their stationary values, denoted by  $P_s^-$ ,  $P_s$ , and  $K_s$ , respectively [20]. The  $P_s^-$  can be computed by solving following DARE. Having  $P_s^-$ , stationary gain  $K_s$  and estimation covariance  $P_s$  is computed as follows:

$$P_s^- = G_s Q_s G_s^T + A_s (P_s^- - P_s^- H_s^T (H_s P_s^- H_s^T + M_s R_s M_s^T)^{-1} H_s P_s^-) A_s^T,$$
(39)

$$K_s = P_s^- H_s^T (H_s P_s^- H_s^T + M_s R_s M_s^T)^{-1}, (40)$$

$$P_s = (I - K_s H_s) P_s^- \tag{41}$$
